## Introduction

- o The Earth's ionosphere is the upper layer of our atmosphere the border between us and outer space. It is constantly changing due to the Sun's energy ionizing various particles, but it does not follow the daily cycle of the Sun consistently.
- o There is ionospheric variability present that can be attributed to winds in the thermosphere. (Figure 1)[1,3]
- The aim of this investigation is to understand how the changes in these upper atmospheric winds cause fluctuations in the in situ plasma densities of the ionosphere.

### Data and Methods

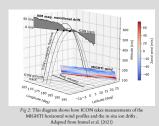

For this analysis, the data from ICON mission's Ion Velocity Meter (IVM) and MIGHTI were utilized.

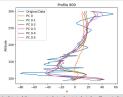

- . IVM measures the plasma densities and drifts. [2]
- · MIGHTI data comprises of the horizontal neutral wind profiles from the altitude range of 90-300 km. For this analysis, the zonal winds were utilized. [2]
- · The data is taken from only the "perfect" conjunctions at equatorial crossing. (Figure 2)

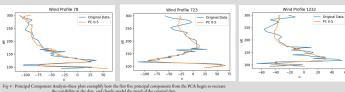

- . The IVM data is filtered by using quality flags, and only considering later local times (hours 11-16).
- · The MIGHTI data consists of 84 different altitude profiles spread through the range, and 80 of these are used for the analysis (alts 2-82).

#### Linear Regression Modeling

- . Using the zonal wind profiles and Python's SKLearn, the data is split into training and test sets to create a linear regression model predictor that will generates a predicted meridional ion drift profile based on the zonal winds.
- · Due to overfitting, a dimensionality reduction methodology (principal component analysis) is used to increase model efficiency (Figures 3,4).

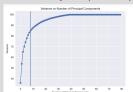

### Change in Meridional Drift Predictor

- · After developing a strong understanding of how PCA works, this is further utilized to create a linear regression model to predict the change in the meridional drift from the change in the zonal winds.
- To isolate day-to-day variability from other kinds of variability (seasonal, longitudinal, etc.), a change in time interval was defined such that it yields the change of the wind at nearly the same place and local time, separated by almost 1 day (24-24.15 hours).

· When the PCA is applied, a number of components needs to be selected. This is the number of features that will be used in the linear regression model to optimize bias-variance tradeoff and ensure there is no overfitting/underfitting. (Figure 4,5)

Fig. 5: Principal Component Selection
The plot showcases the number of features (the number of principal components- which are the 80 altitude profiles) years their contribution to the variance. If all 80 features are used, the model encapsulates 100% of the ariance. In this case, the 8th principal component is used to capture 85.66% of the variance

Fig 6: Principal Component Linear Regression Model Performance
The plot below validates the choice of the principal component number. As we can see from the  $r^22$  value (which is a metric of how well the change in zonal winds are able to capture the variance in the meridional drifts) for both the train and test set, after the 8th component, the

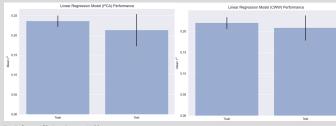

The r^2 value was used to evaluate the model performance on both the training and test sets. They seem to once again, qualitatively match the Immel et al. [2021], conclusions that were made that the found correlations of r ~ 0.47 to 0.56, which is consistent with the r^2 from this model of ~ 0.2. [1]

r^2 for Training Set Using SKLearn PCA 0.2031581138350801 r^2 for Test Set Using SKLearn PCA 0.29842189016985077

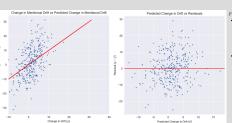

#### Comparative Study: Conductivity Weighted Winds

- As studied in Immel et al. [2021], the conductivity-weighted winds- the Hall and Pederson profiles can be used to model the meridional drifts. [1]
- · To create a comparison between the PCA-based linear regression model, a weighted-wind model was created. For this model, the mean of the wind was taken over the crossings, and once again, the change in this mean in the 1 day interval was determined.
- · To evaluate the performance of these models multiple randomized train test splits were used. Then, finding the r^2 value of each one of these model instances led to the mean and standard deviation being determined.

## Conclusions

- Fig 7: Linear Regression Model: Prediction results
   The plot on the left showcases how the change in predicted meridional drifts correlates with the actual change in measured values from the IVM data. As shown in the plot, there is a positive correlation between the predictions and the actual values, and overall the model
- difference between the measured changes in meridio drifts from the IVM data and the predictions made us x-axis, further showing that a linear regression model ca
- o A dimensionality-reduced principal component regression model can be used to effectively create a predictor for the meridional ion drifts using the zonal winds.
- o The performance of the PCA model is comparable to that of one that utilizes the Hall and Pederson conductivity-weighted winds- without making any assumptions about the conductivity, while the conductivity-weighted wind (CWW) approach does need to assume a conductivity profile.

#### Sensitivity Profiles

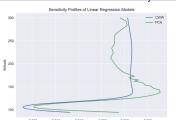

Fig 8: Sensitivity Profiles The plot showcases the dependence of the linear regression model on the features from the PCA components and the Hall and Pederson winds. Both models have 'weightage' profiles that follow a similar trend throughout all of the selected altitude zonal wind

Linear regression can be modeled by an equation, and the coefficients (or 'weights') in this equation are what build up the sensitivity profile (as shown in Fig 8).

 $\Delta v = c_0 * \Delta u_0 + c_1 * \Delta u_1 + \dots$ 

### Ongoing Work

- o For this study, only the horizontal neutral wind profiles were utilized. Adding on the meridional winds may provide additional insights into correlations between the winds and the meridional ion drifts.
- o The PCA procedure's efficiency increases when the datasets it is being used upon are scaled and centered- so a methodology to scale this data could be used to improve model performance.
- A similar analysis could be run on the ion density data to understand how the changes in the densities are related to the change in the
- o The PCA component profiles hold information that is correlated to other factors that influence the meridional drifts (e.g. local time), and investigating these could generate a better understanding of the ion drifts.
